

Iterated Local Search

Helena R. Lourenço, Olivier C. Martin, and Thomas Stützle

1 Introduction

The importance of high performance algorithms for tackling difficult optimization problems cannot be understated, and in many cases the most methods effective are metaheuristics. When designing a metaheuristic, it is preferable that it be simple, both conceptually and in practice. Naturally, it also must lead to effective algorithms, and if possible, general purpose. If we think of a metaheuristic as simply a construction for guiding (problem-specific) heuristics, the ideal case is when the metaheuristic can be used without *any* problem-dependent knowledge.

As metaheuristics have become more and more sophisticated, this ideal case has been pushed aside in the quest for greater performance. As a consequence, problem-specific knowledge (in addition to that built into the heuristic being guided) must now be incorporated into metaheuristics in order to reach the state of the art level. Unfortunately, this makes the boundary between heuristics and *metaheuristics* fuzzy, and we run the risk of losing both simplicity and generality. To counter this, we appeal to modularity and try to decompose a metaheuristic algorithm into a few parts, each with its own specificity. In particular, we would like to have a totally general purpose part, while any problem-specific knowledge built into the metaheuristic would be restricted to another part. Finally, to the extent possible, we prefer to leave untouched the embedded heuristic (which is to be “guided”) because of its potential complexity. One can also consider the case where this heuristic is only available through an object module, the source code being proprietary;

it is then necessary to be able to treat it as a “black-box” routine. Iterated local search provides a simple way to satisfy all these requirements.

The essence of the iterated local search metaheuristic can be given in a nut-shell: one *iteratively* builds a sequence of solutions generated by the embedded heuristic, leading to far better solutions than if one were to use repeated random trials of that heuristic. This simple idea [9] has a long history, and its rediscovery by many authors has lead to many different names for iterated local search like *iterated descent* [8, 7], *large-step Markov chains* [61], *iterated Lin-Kernighan* [45], *chained local optimization* [60], or combinations of these [1] ... Readers interested in these historical developments should consult the review [46]. For us, there are two main points that make an algorithm an iterated local search: (i) there must be a single chain that is being followed (this then excludes population-based algorithms); (ii) the search for better solutions occurs in a reduced space defined by the output of a black-box heuristic. In practice, local search has been the most frequently used embedded heuristic, but in fact any optimizer can be used, be it deterministic or not.

The purpose of this review is to give a detailed description of iterated local search and to show where it stands in terms of performance. So far, in spite of its conceptual simplicity, it has lead to a number of state-of-the-art results without the use of too much problem-specific knowledge; perhaps this is because iterated local search is very malleable, many implementation choices being left to the developer. We have organized this chapter as follows. First we give a high-level presentation of iterated local search in Section 2. Then we discuss the importance of the different parts of the metaheuristic in Section 3, especially the subtleties associated with perturbing the solutions. In Section 4 we go over past work testing iterated local search in practice, while in Section 5 we discuss similarities and differences between iterated local search and other metaheuristics. The chapter closes with a summary of what has been achieved so far and an outlook on what the near future may look like.

2 Iterating a local search

2.1 General framework

We assume we have been given a problem-specific heuristic optimization algorithm that from now on we shall refer to as a local search (even if in fact it is not a true local search). This algorithm is implemented via a computer routine that we call `LocalSearch`. The question we ask is “Can such an algorithm be improved by the use of iteration?”. Our answer is “YES”, and in fact the improvements obtained in practice are usually significant. Only in rather

Fig. 1 Probability densities of costs. The curve labeled s gives the cost density for all solutions, while the curve labeled s^* gives it for the solutions that are local optima.

pathological cases where the iteration method is “incompatible” with the local search will the improvement be minimal. In the same vein, in order to have the *most* improvement possible, it is necessary to have some understanding of the way the `LocalSearch` works. However, to keep this presentation as simple as possible, we shall ignore for the time being these complications; the additional subtleties associated with tuning the iteration to the local search procedure will be discussed in Section 3. Furthermore, all issues associated with the actual speed of the algorithm are omitted in this first section as we wish to focus solely on the high-level architecture of iterated local search.

Let \mathcal{C} be the cost function of our combinatorial optimization problem; \mathcal{C} is to be *minimized*. We label candidate solutions or simply “solutions” by s , and denote by \mathcal{S} the set of all s (for simplicity \mathcal{S} is taken to be finite, but it does not matter much). Finally, for the purposes of this high-level presentation, it is simplest to assume that the local search procedure is deterministic and memoriless:¹ for a given input s , it always outputs the same solution s^* whose cost is less or equal to $\mathcal{C}(s)$. `LocalSearch` then defines a many to one mapping from the set \mathcal{S} to the smaller set \mathcal{S}^* of locally optimal solutions s^* . To have a pictorial view of this, introduce the “basin of attraction” of a local minimum s^* as the set of s that are mapped to s^* under the local search routine. `LocalSearch` then takes one from a starting solution to a solution at the bottom of the corresponding basin of attraction.

Now take an s or an s^* at random. Typically, the distribution of costs found has a very rapidly rising part at the lowest values. In Figure 1 we show the kind of distributions found in practice for combinatorial optimization

¹ The reader can check that very little of what we say really uses this property, and in practice, many successful implementations of iterated local search have non-deterministic local searches or include memory.

problems having a finite solution space. The distribution of costs is bell-shaped, with a mean and variance that is significantly smaller for solutions in \mathcal{S}^* than for those in \mathcal{S} . As a consequence, it is much better to use local search than to sample randomly in \mathcal{S} if one seeks low cost solutions. The essential ingredient necessary for local search is a neighborhood structure. This means that \mathcal{S} is a “space” with some topological structure, not just a set. Having such a space allows one to move from one solution s to a better one in an intelligent way, something that would not be possible if \mathcal{S} were just a set.

Now the question is how to go beyond this use of `LocalSearch`. More precisely, given the mapping from \mathcal{S} to \mathcal{S}^* , how can one further reduce the costs found without opening up and modifying `LocalSearch`, leaving it as a “black box” routine?

2.2 *Random restart*

The simplest possibility to improve upon a cost found by `LocalSearch` is to repeat the search from another starting point. Every s^* generated is then independent, and the use of multiple trials allows one to reach into the lower part of the distribution. Although such a “random restart” approach with independent samplings is sometimes a useful strategy (in particular when all other options fail), it breaks down as the instance size grows because in that limit the tail of the distribution of costs collapses. Indeed, empirical studies [46] and general arguments [77] indicate that local search algorithms on large generic instances lead to costs that: (i) have a mean that is a fixed percentage excess above the optimum cost; (ii) have a *distribution* that becomes arbitrarily peaked about the mean when the instance size goes to infinity. This second property makes it impossible in practice to find an s^* whose cost is even a little bit lower percentage-wise than the typical cost. Note however that there do exist many solutions of significantly lower cost, it is just that *random* sampling has a lower and lower probability of finding them as the instance size increases. To reach those configurations, a biased sampling is necessary; this is precisely what is accomplished by a stochastic search.

2.3 *Searching in \mathcal{S}^**

To overcome the problem just mentioned associated with large instance sizes, reconsider what local search does: it takes one from \mathcal{S} where \mathcal{C} has a large mean to \mathcal{S}^* where \mathcal{C} has a smaller mean. It is then most natural to invoke recursion: use local search to go from \mathcal{S}^* to a smaller space \mathcal{S}^{**} where the mean cost will be still lower! That would correspond to an algorithm with one

local search nested inside another. Such a construction could be iterated to as many levels as desired, leading to a hierarchy of nested local searches. But upon closer scrutiny, we see that the problem is precisely how to formulate local search beyond the lowest level of the hierarchy: local search requires a neighborhood structure and this is not *a priori* given. The fundamental difficulty is to define neighbors in \mathcal{S}^* so that they can be enumerated and accessed efficiently. Furthermore, it is desirable for nearest neighbors in \mathcal{S}^* to be relatively close when using the distance in \mathcal{S} ; if this were not the case, a stochastic search on \mathcal{S}^* would have little chance of being effective.

Upon further thought, it transpires that one can introduce a good neighborhood structure on \mathcal{S}^* as follows. First, one recalls that a neighborhood structure on a set \mathcal{S} directly induces a neighborhood structure on *subsets* of \mathcal{S} : two subsets are nearest neighbors simply if they contain solutions that are nearest neighbors. Second, take these subsets to be the basins of attraction of the s^* ; in effect, we are lead to identify any s^* with its basin of attraction. This then immediately gives the “canonical” notion of neighborhood on \mathcal{S}^* , notion which can be stated in a simple way as follows: s_1^* and s_2^* are neighbors in \mathcal{S}^* if their basins of attraction “touch” (*i.e.*, contain nearest-neighbor solutions in \mathcal{S}). Unfortunately this definition has the major drawback that one cannot in practice list the neighbors of an s^* because there is no computationally efficient method for finding all solutions s in the basin of attraction of s^* . Nevertheless, we can *stochastically* generate nearest neighbors as follows. Starting from s^* , create a randomized path in \mathcal{S} , s_1, s_2, \dots, s_i , where s_{j+1} is a nearest neighbor of s_j . Determine the first s_j in this path that belongs to a different basin of attraction so that applying local search to s_j leads to an $s^{*'} \neq s^*$. Then $s^{*'}$ is a nearest-neighbor of s^* .

Given this procedure, we can in principle perform a local search² in \mathcal{S}^* . Extending the argument recursively, we see that it would be possible to have an algorithm implementing nested searches, performing local search on \mathcal{S} , \mathcal{S}^* , \mathcal{S}^{**} , etc... in a hierarchical way. Unfortunately, the implementation of nearest neighbor search at the level of \mathcal{S}^* is much too costly computationally because of the number of times one has to execute `LocalSearch`. Thus we are led to abandon the (stochastic) search for *nearest neighbors* in \mathcal{S}^* ; instead we use a weaker notion of closeness which then allows for a fast stochastic search in \mathcal{S}^* . Our construction leads to a (biased) sampling of \mathcal{S}^* ; such a sampling will be better than a random one if it is possible to find appropriate computational ways to go from one s^* to another. Finally, one last advantage of this modified notion of closeness is that it does not require basins of attraction to be defined; the local search can then incorporate memory or be non-deterministic, making the method far more general.

² Note that the local search finds neighbors stochastically; generally there is no efficient way to ensure that one has tested *all* the neighbors of any given s^* .

Fig. 2 Pictorial representation of iterated local search. Starting with a local minimum s^* , we apply a perturbation leading to a solution s' . After applying `LocalSearch`, we find a new local minimum $s^{*'}$ that may be better than s^* .

2.4 Iterated Local Search

We want to explore \mathcal{S}^* using a walk that steps from one s^* to a “nearby” one, without the constraint of using only nearest neighbors as defined above. Iterated local search (ILS) achieves this heuristically as follows. Given the current s^* , we first apply a change or perturbation that leads to an intermediate state s' (which belongs to \mathcal{S}). Then `LocalSearch` is applied to s' and we reach a solution $s^{*'}$ in \mathcal{S}^* . If $s^{*'}$ passes an acceptance test, it becomes the next element of the walk in \mathcal{S}^* ; otherwise, one returns to s^* . The resulting walk is a case of a stochastic search in \mathcal{S}^* , but where neighborhoods are never explicitly introduced. This iterated local search procedure should lead to good biased sampling as long as the perturbations are neither too small nor too large. If they are too small, one will often fall back to s^* and few new solutions of \mathcal{S}^* will be explored. If on the contrary the perturbations are too large, s' will be random, there will be no bias in the sampling, and we will recover a random restart type algorithm.

The overall ILS procedure is pictorially illustrated in Figure 2. To be complete, let us note that generally the iterated local search walk will not be reversible; in particular one may sometimes be able to step from s_1^* to s_2^* but not from s_2^* to s_1^* . However this “unfortunate” aspect of the procedure does not prevent ILS from being very effective in practice.

Since deterministic perturbations may lead to short cycles (for instance of length 2), one should randomize the perturbations or have them be adaptive so as to avoid this kind of cycling. If the perturbations depend on any of the previous s^* , one has a walk in \mathcal{S}^* with *memory*. Now the reader may have noticed that aside from the issue of perturbations (which use the structure on \mathcal{S}), our formalism reduces the problem to that of a stochastic search on

Algorithm 1 Iterated Local Search.

```

1:  $s_0 = \text{GenerateInitialSolution}$ 
2:  $s^* = \text{LocalSearch}(s_0)$ 
3:  $V_T = \emptyset$ 
4: repeat
5:    $s' = \text{Perturbation}(s^*, \text{history})$ 
6:    $s^{*'} = \text{LocalSearch}(s')$ 
7:    $s^* = \text{AcceptanceCriterion}$ 
8: until termination condition met

```

\mathcal{S}^* . Then all of the bells and whistles (diversification, intensification, tabu, adaptive perturbations and acceptance criteria, etc...) that are commonly used in that context may be applied here. This leads us to define iterated local search algorithms as metaheuristics having the high level architecture as given by Algorithm 1.

In practice, much of the potential complexity of ILS is hidden in the history dependence. If there happens to be no such dependence, the walk has no memory:³ the perturbation and acceptance criterion do not depend on any of the solutions visited previously during the walk, and one accepts or not $s^{*'}$ with a fixed rule. This leads to random walk dynamics on \mathcal{S}^* that are “Markovian”, the probability of making a particular step from s_1^* to s_2^* depending only on s_1^* and s_2^* . Most of the work using ILS has been of this type, though studies show unambiguously that incorporating memory enhances performance [82].

Staying within Markovian walks, the most basic acceptance criteria will use only the difference in the costs of s^* and $s^{*'}$; this type of dynamics for the walk is then very similar in spirit to what occurs in simulated annealing. A limiting case of this is to accept only improving moves, as happens in simulated annealing at zero temperature; the algorithm then does (stochastic) descent in \mathcal{S}^* . If we add to such a method a CPU time criterion to stop the search for improvements, the resulting algorithm pretty much has two nested local searches; to be precise, it has a local search operating on \mathcal{S} embedded in a stochastic search operating on \mathcal{S}^* . More generally, one can extend this type of algorithm to more levels of nesting, having a different stochastic search algorithm for \mathcal{S}^* , \mathcal{S}^{**} etc... Each level would be characterized by its own type of perturbation and stopping rule; to our knowledge, such a construction has never been attempted.

We can summarize this section by saying that the potential power of iterated local search lies in its *biased* sampling of the set of local optima. The efficiency of this sampling depends both on the kinds of perturbations and on the acceptance criteria. Interestingly, even with the most naïve implementations of these parts, iterated local search is much better than random restart. But still much better results can be obtained if the iterated local

³ Recall that to simplify this section’s presentation, the local search is assumed to have no memory.

search modules are optimized. First, the acceptance criteria can be adjusted empirically as in simulated annealing without knowing anything about the problem being optimized. This kind of optimization will be familiar to any user of metaheuristics, though the questions of memory may become quite complex. Second, the **Perturbation** routine can incorporate as much problem-specific information as the developer is willing to put into it. In practice, a rule of thumb can be used as a guide: “a good perturbation transforms one excellent solution into an excellent starting point for a local search”. Together, these different aspects show that iterated local search algorithms can have a wide range of complexity, but complexity may be added progressively and in a modular way. (Recall in particular that all of the fine-tuning that resides in the embedded local search can be ignored if one wants, and it does not appear in the metaheuristic per-se.) This makes iterated local search an appealing metaheuristic for both academic and industrial applications. The cherry on the cake is speed: as we shall soon see, one can perform k local searches embedded within an iterated local search *much* faster than if the k local searches are run within random restart.

3 Getting high performance

Given all these advantages, we hope the reader is now motivated to go on and consider the more nitty-gritty details that arise when developing an ILS algorithm for a new application. In this section, we will illustrate the main issues that need to be tackled when optimizing an ILS algorithm in order to achieve high performance.

There are four components to consider: **GenerateInitialSolution**, **LocalSearch**, **Perturbation**, and **AcceptanceCriterion**. Before attempting to develop a state-of-the-art algorithm, it is relatively straight-forward to develop a more basic version of ILS. Indeed, (i) one can start with a random solution or one returned by some greedy construction heuristic; (ii) for most problems a local search algorithm is readily available; (iii) for the perturbation, a random move in a neighborhood of higher order than the one used by the local search algorithm can be surprisingly effective; and (iv) a reasonable first guess for the acceptance criterion is to force the cost to decrease, corresponding to a first-improvement descent in the set \mathcal{S}^* . Basic ILS implementations of this type usually lead to much better performance than random restart approaches. The developer can then run this basic ILS to build his intuition and try to improve the overall algorithm performance by improving each of the four modules. This should be particularly effective if it is possible to take into account the specificities of the combinatorial optimization problem under consideration. In practice, this tuning is easier for ILS than for memetic algorithms or to name but these metaheuristics. The reason may be that the complexity of ILS is reduced by its modularity, the function of each component being

relatively easy to understand. Finally, the last task to consider is the overall optimization of the ILS algorithm; indeed, the different components affect one another and so it is necessary to understand their interactions. However, because these interactions are so problem dependent, we wait till the end of this section before discussing that kind of “global” optimization.

Perhaps the main message here is that the developer can choose the level of optimization he wants. In the absence of any optimizations, ILS is a simple, easy to implement, and quite effective metaheuristic. But with further work on its four components, ILS can often be turned into a very competitive or even state of the art algorithm.

3.1 Initial solution

Local search applied to the initial solution s_0 gives the starting point s_0^* of the walk in the set \mathcal{S}^* . Starting with a good s_0^* can be important if high-quality solutions are to be reached *as fast as possible*.

Standard choices for s_0 are either a random initial solution or a solution returned by a greedy construction heuristic. A greedy initial solution s_0 has two main advantages over random starting solutions: (i) when combined with local search, greedy initial solutions often result in better quality solutions s_0^* ; (ii) a local search from greedy solutions takes, on average, less improvement steps and therefore the local search requires less CPU time.⁴

The question of an appropriate initial solution for (random restart) local search carries over to ILS because of the dependence of the walk in \mathcal{S}^* on the initial solution s_0^* . Indeed, when starting with a random s_0 , ILS may take several iterations to catch up in quality with runs using an s_0^* obtained by a greedy initial solution. Hence, for short computation times the initial solution is certainly important to achieve the highest quality solutions possible. For larger computation times, the dependence on s_0 of the final solution returned by ILS reflects just how fast, if at all, the memory of the initial solution is lost when performing the walk in \mathcal{S}^* .

Let us illustrate the tradeoffs between random and greedy initial solutions when using an ILS algorithm for the permutation flow shop problem (FSP) [79]. That ILS algorithm uses a straight-forward local search implementation, random perturbations, and always applies **Perturbation** to the best solution found so far. In Figure 3 we show how the average solution cost (makespan) evolves with the number of iterations for two instances. The aver-

⁴ Note that the best possible greedy initial solution need not be the best choice when combined with a local search. For example, in [46], it is shown that the combination of the Clarke-Wright starting tour (one of the best performing TSP construction heuristics) with local search resulted in worse local optima than starting from random initial solutions when using 3-opt. Additionally, greedy algorithms which generate very high quality initial solutions can be quite time-consuming.

Fig. 3 The plots show the average solution cost (makespan on the y -axis) as a function of CPU time (given on the x -axis) for an ILS algorithm applied to the FSP on instances `ta051` and `ta056`.

ages are for 10 independent runs when starting from random initial solutions or from initial solutions returned by the NEH heuristic [69]. (NEH is one of the best performing constructive heuristics for the FSP.) For short runs, the curve for the instance on the right shows that the NEH initial solutions lead to better average solution cost than random initial solutions. But at longer times, the picture is not so clear, sometimes random initial solutions lead to better average results as we see on the instance on the left. This kind of test was also performed for ILS applied to the TSP [1]. Again it was observed that the initial solution had a significant influence on quality for short to medium sized runs.

In general, there will not always be a clear-cut answer regarding the best choice of an initial solution, but greedy initial solutions appear to be recommendable when one needs low-cost solutions quickly. For much longer runs, the initial solution seems to be less relevant, so the user can choose the initial solution that is the easiest to implement. If, however, one has an application where the influence of the initial solution does persist for long times, probably the ILS walk is having difficulty in exploring \mathcal{S}^* and so other perturbations or acceptance criteria should be considered.

3.2 Perturbation

The main drawback of local descent is that it gets trapped in local optima that are significantly worse than the global optimum. Much like simulated annealing, ILS escapes from local optima by applying perturbations to the current local minimum. We will refer to the *strength* of a perturbation as the number of solution components which are modified. For instance for the TSP, it is the number of edges that are changed in the tour, while in the flow

shop problem, it is the number of jobs which are moved in the perturbation. Generally, the local search should not be able to undo the perturbation, otherwise one will fall back into the local optimum just visited. Surprisingly often, a *random* move in a neighborhood of higher order than the one used by the local search algorithm can achieve this and will lead to a satisfactory algorithm. Still better results can be obtained if the perturbations take into account properties of the problem and are well matched to the local search algorithm.

By how much should the perturbation change the current solution? If the perturbation is too strong, ILS may behave like a random restart, so better solutions will only be found with a very low probability. On the other hand, if the perturbation is too small, the local search will often fall back into the local optimum just visited and the diversification of the search space will be very limited. An example of a simple but effective perturbation for the TSP is the *double-bridge move*. This perturbation cuts four edges (and is thus of “strength” 4) and introduces four new ones as shown in Figure 4. Notice that each bridge is a 2-change, but neither of the 2-changes individually keeps the tour connected. Nearly all ILS studies of the TSP have incorporated this kind of perturbation, and it has been found to be effective for all instance sizes. This is almost certainly because it changes the topology of the tour and can operate on quadruples of very distant cities, whereas local search always modifies the tour among nearby cities. In effect, the double-bridge perturbation cannot be undone easily, neither by simple local search algorithms such as **2-opt** or **3-opt**, nor by most local search algorithms based on the Lin-Kernighan heuristic [54], which is currently the champion local search algorithm for the TSP. (Only very few local searches include such double-bridge changes in the search, the best known being the Lin-Kernighan implementation of Helsgaun [40].) Furthermore, this perturbation does not increase much the tour length, so even if the current solution is very good, one is almost sure the next one will be good, too. These two properties of the perturbation – its small strength and its fundamentally different nature from the changes used in local search – make the TSP the perfect application for iterated local search. But for other problems, finding an effective perturbation may be more difficult.

We will now consider optimizing the perturbation assuming the other modules to be fixed. In problems like the TSP, one can hope to have a satisfactory ILS when using perturbations of fixed size (independent of the instance size). On the contrary, for more difficult problems, fixed-strength perturbations may lead to poor performance. Of course, the strength of the perturbations used is not the whole story; their nature is almost always very important and will also be discussed. Finally we will close by pointing out that the perturbation strength has an effect on the speed of the local search: weak perturbations usually lead to faster execution of **LocalSearch**. All these different aspects need to be considered when optimizing this module.

Fig. 4 Schematic representation of the double-bridge move. The four dotted edges are removed and the remaining parts A, B, C, D are reconnected by the dashed edges.

3.2.1 Perturbation strength

For some problems, an appropriate perturbation strength is very small and seems to be rather independent of the instance size. This is the case for both the TSP and the FSP, and interestingly iterated local search for these problems is very competitive with today's best metaheuristic methods. We can also consider other problems where instead one is driven to large perturbation sizes. Consider the example of an ILS algorithm for the quadratic assignment problem (QAP). We use an embedded **2-opt** local search algorithm, the perturbation is a random exchange of the location of k items, where k is an adjustable parameter, and **Perturbation** always modifies the best solution found so far. We applied this ILS algorithm to QAPLIB instances⁵ from four different classes of QAP instances [83]; computational results are given in Table 1. A first observation is that the best perturbation size is strongly dependent on the particular instance. For two of the instances, the best performance was achieved when as many as 75% of the solution components were altered by the perturbation. Additionally, for a too small perturbation strength, the ILS performed worse than random restart (corresponding to the perturbation strength n). However, the fact that random restart for the QAP may perform—on average—better than a basic ILS algorithm is a bit misleading: in the next section we will show that by simply modifying a bit the acceptance criterion, ILS becomes far better than random restart. Thus one should keep in mind that the optimization of an iterated local search may require more than the optimization of the individual components.

⁵ QAPLIB is accessible at <http://www.seas.upenn.edu/qaplib>.

Table 1 The first column is the name of the QAP instance; the number gives its size n . The successive columns are for perturbation sizes 3, $n/12$, \dots , n . A perturbation of size n corresponds to random restart. The table shows the mean solution cost, averaged over 10 independent runs for each instance. The CPU-time for each trial is 30 sec. for **kra30a**, 60 sec. for **tai60a** and **sko64**, and 120 sec. for **tai60b** on a Pentium III 500 MHz PC.

instance	3	$n/12$	$n/6$	$n/4$	$n/3$	$n/2$	$3n/4$	n
kra30a	2.51	2.51	2.04	1.06	0.83	0.42	0.0	0.77
sko64	0.65	1.04	0.50	0.37	0.29	0.29	0.82	0.93
tai60a	2.31	2.24	1.91	1.71	1.86	2.94	3.13	3.18
tai60b	2.44	0.97	0.67	0.96	0.82	0.50	0.14	0.43

3.2.2 Adaptive perturbations

The behavior of ILS for the QAP and also for other combinatorial optimization problems [41, 79] shows that there is no *a priori* single best size for the perturbation. This motivates the possibility of modifying the perturbation strength and adapting it *during* the run.

One possibility to do so is to exploit the search history. For the development of such schemes, inspiration can be taken from what is done in the context of [6, 5]. In particular, Battiti and Protasi proposed [5] a reactive search algorithm for MAX-SAT which fits perfectly into the ILS framework. They perform a “directed” perturbation scheme which is implemented by a tabu search algorithm and after each perturbation they apply a standard local descent algorithm.

Another way of adapting the perturbation is to change deterministically its strength during the search. One particular example of such an approach is employed in the scheme called *basic variable neighborhood search* (basic VNS) [66, 38]; we refer to Section 5 for some explanations on VNS. Other examples arise in the context of [36]. In particular, ideas such as strategic oscillations may be useful to derive more effective perturbations; that is also the spirit of the reactive search algorithm previously mentioned.

3.2.3 More complex perturbation schemes

Perturbations can be more complex than changes in a higher order neighborhood. One rather general procedure to generate s' from the current s^* is as follows. First, gently modify the definition of the instance, e.g. via the parameters defining the various costs. Second, for this modified instance, run **LocalSearch** using s^* as input; the output is the perturbed solution s' . Interestingly, this is the method proposed in the oldest ILS work we are aware of: in [9], Baxter tested this approach with success on a location problem. This idea seems to have been rediscovered later by Codenotti et al. in the context of the TSP. Those authors [18] first change slightly the city coordinates. Then

they apply the local search to s^* using the perturbed city locations, obtaining the new tour s' . Finally, running `LocalSearch` on s' using the *unperturbed* city coordinates, they obtain the new candidate tour $s^{*'}$.

Other sophisticated ways to generate good perturbations consist in optimizing a sub-part of the problem. If this task is difficult for the embedded heuristic, good results can follow. Such an approach was proposed by Lourenço [55] in the context of the job shop scheduling problem (JSP). Her perturbation schemes are based on defining one- or two-machine sub-problems by fixing a number of variables in the current solution and solving these sub-problems, either heuristically [56] or to optimality using for instance Carlier’s exact algorithm [15] or the early-late algorithm [56]. These schemes work well because: (i) local search is unable to undo the perturbations; (ii) after the perturbation, the solutions tend to be very good and also have “new” parts that are optimized. More recently, evolutionary algorithms have been used to generate perturbations for ILS algorithms [58]. The idea in this approach is generate a small population of solutions by perturbing the best so far solution as the initial solution of a short run of a GA and then to use the best solution found in this process as a new starting solution for the local search.

3.2.4 Speed

In the context of “easy” problems where ILS can work very well with weak (fixed size) perturbations, there is another reason why that metaheuristic can perform much better than random restart: *Speed*. Indeed, `LocalSearch` will usually execute much faster on a solution obtained by applying a small perturbation to a local optimum than on a random solution. As a consequence, iterated local search can run many more local searches than can random restart in the same CPU time. As a qualitative example, consider again Euclidean TSPs. $\mathcal{O}(n)$ local changes have to be applied by the local search to reach a local optimum from a random start, whereas empirically a nearly constant number is necessary in ILS when using the s' obtained with the double-bridge perturbation. Hence, in a given amount of CPU time, ILS can sample many more local optima than can random restart. This *speed factor* can give ILS a considerable advantage over other restart schemes.

Let us illustrate this speed factor quantitatively. We compare for the TSP the number of local searches performed in a given amount of CPU time by: (i) random restart; (ii) ILS using a double-bridge move; (iii) ILS using five simultaneous double-bridge moves. (For both ILS implementations, we used random starts and the routine `AcceptanceCriterion` accepted only shorter tours.) For our numerical tests we used a fast `3-opt` implementation with standard speed-up techniques. In particular, it used a fixed radius nearest neighbor search within candidate lists of the 40 nearest neighbors for each city and don’t look bits [11, 46, 61]. Initially, all don’t look bits are turned

Table 2 The first column gives the name of the TSP instance, where the number in the identifier specifies the number of cities. The next columns give the number of local searches performed when using: (i) random restart ($\#LS_{RR}$); (ii) ILS with a single double-bridge perturbation ($\#LS_{1-DB}$); (iii) ILS with a five double-bridge perturbation ($\#LS_{5-DB}$). All algorithms were run 120 secs. on a Pentium 266 MHz PC.

off (set to 0). If for a node no improving move can be found, its don't look bit is turned on (set to 1) and the node is not considered as a starting node for finding an improving move in the next iteration. When an arc incident to a node is changed by a move, the node's don't look bit is turned off again. In addition, when running ILS, after a perturbation we only turn off the don't look bits of the 25 cities around each of the four breakpoints in a current tour. All three algorithms were run for 120 seconds on a 266 MHz Pentium II processor on a set of TSPLIB⁶ instances ranging from 100 up to 5915 cities. Results are given in Table 2. For the smallest instances, we see that iterated local search ran between 2 and 10 times as many local searches as random restart. This advantage of ILS grows fast with increasing instance size: for the largest instance, the first ILS algorithm ran approximately 260 times as many local searches as random restart in our allotted time. Obviously, this speed advantage of ILS over random restart is strongly dependent on the strength of the perturbation applied. The larger the perturbation size, the more the solution is modified and generally the longer the subsequent local search takes. This fact is intuitively obvious and is confirmed in Table 2.

In summary, the optimization of the perturbations depends on many factors, and problem-specific characteristics play a central role. Finally, it is important to keep in mind that the perturbations also interact with the other components of ILS. We will discuss these interactions in Section 3.5

⁶ TSPLIB is accessible at www.iwr.uni-heidelberg.de/groups/comopt/software/TSPLIB95.

3.3 Acceptance criterion

ILS does a randomized walk in \mathcal{S}^* , the space of the local minima. The perturbation mechanism together with the local search defines the possible transitions between a current solution s^* in \mathcal{S}^* to a “neighboring” solution $s^{*'} also in \mathcal{S}^* . The procedure **AcceptanceCriterion** then determines whether $s^{*'}$ is accepted or not as the new current solution. **AcceptanceCriterion** has a strong influence on the nature and effectiveness of the walk in \mathcal{S}^* . Roughly, it can be used to control the balance between intensification and diversification of that search. A simple way to illustrate this is to consider a Markovian acceptance criterion. A very strong intensification is achieved if only better solutions are accepted. We call this acceptance criterion **Better** and it is defined for minimization problems as:$

$$\mathbf{Better}(s^*, s^{*'}, history) = \begin{cases} s^{*' & \text{if } \mathcal{C}(s^{*'}) < \mathcal{C}(s^*) \\ s^* & \text{otherwise} \end{cases} \quad (1)$$

At the opposite extreme is the random walk acceptance criterion (denoted by **RW**) which always applies the perturbation to the most recently visited local optimum, irrespective of its cost:

$$\mathbf{RW}(s^*, s^{*'}, history) = s^{*' \quad (2)$$

This criterion clearly favors diversification over intensification.

Many intermediate choices between these two extreme cases are possible. In one of the first ILS algorithms, the large-step Markov chains algorithm proposed by Martin, Otto, and Felten [61, 62], a simulated annealing type acceptance criterion was applied. We call it **LSMC**($s^*, s^{*'}, history$). In particular, $s^{*'}$ is always accepted if it is better than s^* . Otherwise, if $s^{*'}$ is worse than s^* , $s^{*'}$ is accepted with probability $\exp\{(\mathcal{C}(s^*) - \mathcal{C}(s^{*'}))/T\}$ where T is a parameter called temperature and it is usually lowered during the run as in simulated annealing. Note that **LSMC** approaches the **RW** acceptance criterion if T is very high, while at very low temperatures **LSMC** is similar to the **Better** acceptance criterion. An interesting possibility for **LSMC** is to allow non-monotonic temperature schedules as proposed in [43] for simulated annealing or in tabu thresholding [34]. This can be most effective if it is done using memory: when further intensification no longer seems useful, increase the temperature to do diversification for a limited time, then resume intensification. Of course, just as in tabu search, it is desirable to do this in an automatic and self-regulating manner [36].

A very limited usage of memory in the acceptance criteria is to completely restart the ILS algorithm when the intensification seems to have become ineffective. (Of course this is a rather extreme way to switch from intensification to diversification). For instance one can restart the ILS algorithm from a new initial solution if no improved solution has been found for a given number of

iterations. The restart of the algorithm can easily be modeled by the acceptance criterion called **Restart**($s^*, s^{*'}, history$). Let i_{last} be the last iteration in which a better solution has been found and i be the iteration counter. Then **Restart**($s^*, s^{*'}, history$) is defined as

$$\text{Restart}(s^*, s^{*'}, history) = \begin{cases} s^{*'} & \text{if } \mathcal{C}(s^{*'}) < \mathcal{C}(s^*) \\ s & \text{if } \mathcal{C}(s^{*'}) \geq \mathcal{C}(s^*) \text{ and } i - i_{last} > i_r \\ s^* & \text{otherwise.} \end{cases} \quad (3)$$

where i_r is a parameter that indicates that the algorithm should be restarted if no improved solution was found for i_r iterations. Typically, s can be generated in different ways. The simplest strategy is to generate a new solution randomly or by a greedy randomized heuristic. Clearly many other ways to incorporate memory may and should be considered, the overall efficiency of ILS being quite sensitive to the acceptance criterion applied. We now illustrate this with two examples.

3.3.1 Example 1: TSP

Let us consider the effect of the two acceptance criteria **RW** and **Better**. We performed our tests on the TSP as summarized in Table 3. We give the average percentage excess over the known optimal solutions when using 10 independent runs on our set of benchmark instances. In addition we also give this excess for the random restart **3-opt** algorithm. First, we observe that both ILS schemes lead to a significantly better average solution quality than random restart using the same local search. This is particularly true for the largest instances, confirming again the claims given in Section 2 Second, given that one expects the good solutions for the TSP to cluster (see Section 3.5), a good strategy should incorporate intensification. It is thus not surprising to see that the **Better** criterion leads to shorter tours than the **RW** criterion.

The runs given in this example are rather short. For much longer runs, the **Better** strategy comes to a point where it no longer finds improved tours. In fact, an analysis of ILS algorithms based on the run-time distributions methodology [42] has shown that such stagnation situations effectively occur and that the performance of the ILS algorithm can be strongly improved by additional diversification mechanisms [81], an occasional restart of the ILS algorithm being the conceptually simplest case.

Table 3 Influence of the acceptance criterion for various TSP instances. The first column gives the name of the TSP instance, where the number in the identifier specifies the number of cities. The next columns give the average excess percentage length of the tours obtained using: random restart (RR), iterated local search with **RW**, and iterated local search with **Better**. The data is averaged over 10 independent runs. All algorithms were run 120 secs. on a Pentium 266 MHz PC.

3.3.2 Example 2: QAP

Let us come back to ILS for the QAP. For this problem we found that the acceptance criterion **Better** together with a (poor) choice of the perturbation strength could result in worse performance than random restart. In Table 4 we give results for the same ILS algorithm except that we now also consider the use of the **RW** and **Restart** acceptance criteria. We see that the ILS algorithm using these modified acceptance criteria are much better than random restart, the only exception being **RW** with a small perturbation strength on **tai60b**.

This example shows that there are strong inter-dependences between the perturbation strength and the acceptance criterion. Rarely is this inter-dependence completely understood. But, as a general rule of thumb, when it is necessary to allow for diversification, we believe it is best to do so by accepting numerous small perturbations rather than by accepting one large perturbation.

Most of the acceptance criteria applied so far in ILS algorithms are either fully Markovian or make use of the search history in a very limited way. We expect that there will be many more ILS applications in the future making strong use of the search history; in particular, alternating between intensification and diversification is likely to be an essential feature in these applications.

Table 4 Further tests on the QAP benchmark problems using the same perturbations and CPU times as before; given is the mean solution cost, averaged over 10 independent runs for each instance. Here we consider three different choices for the acceptance criterion. Clearly, the inclusion of diversification significantly lowers the mean cost found.

3.4 Local search

So far we have treated the local search algorithm as a black box, which is called many times by ILS. Since the behavior and performance of the overall ILS algorithm is quite sensitive to the choice of the embedded heuristic, one should optimize this choice whenever possible. In practice, there may be many quite different algorithms that can be used for the embedded heuristic. (As mentioned at the beginning of the chapter, the heuristic need not even be a local search.) One might think that the better the local search, the better the corresponding ILS. Often this is true. For instance in the context of the TSP, Lin-Kernighan [54] is a better local search than 3-opt which itself is better than 2-opt [46]. Using a fixed type of perturbation such as the double-bridge move, one finds that iterated Lin-Kernighan gives better solutions than iterated 3-opt which itself gives better solutions than iterated 2-opt [46, 81]. But if we assume that the total computation time is fixed, it might be better to apply more frequently a faster but less effective local search algorithm than a slower and more powerful one. Clearly which choice is best depends on just how much more time is needed to run the better heuristic. If the speed difference is not large, for instance if it is independent of the instance size, then it is usually worth using the better heuristic. This is the most frequent case; for instance in the TSP, 3-opt is a bit slower than 2-opt, but the improvement in quality of the tours is well worth the extra CPU time, be it using random restart or iterated local search. The same comparison applies to using L-K rather than 3-opt. However, there are other cases where the increase in CPU time is so large compared to the improvement in solution quality that it is best not to use the “better” local search. For example, again in the context of the TSP, it is known that 4-opt gives slightly better solutions than 3-opt,

but in standard implementations it is $O(n)$ times slower (n being the number of cities). It is then better not to use 4-opt as the local search embedded in ILS.

There are also other aspects that should be considered when selecting a local search. Clearly, there is not much point in having an excellent local search if it will systematically undo the perturbation; however this issue is one of globally optimizing iterated local search, so it will be postponed till the next sub-section. Another important aspect is whether one can really get the speed-ups that were mentioned in sub-section 3.2. There we saw that a standard trick for `LocalSearch` was to introduce don't look bits. These give a large gain in speed if the bits can be reset also after the application of the perturbation. This requires that the developer be able to access the source code of `LocalSearch`. A state of the art ILS will take advantage of all possible speed-up tricks, and thus the `LocalSearch` most likely will not be a true black box.

Finally, there may be some advantages in allowing `LocalSearch` to sometimes generate worse solutions. For instance, if we replace the local search heuristic by tabu search or short simulated annealing runs, the corresponding ILS may perform better. This seems most promising when standard local search methods perform poorly. Such is indeed the case in the job-shop scheduling problem: the use of tabu search as the embedded heuristic gives rise to a very effective iterated local search [57].

3.5 Global optimization of ILS

So far, we have considered representative issues arising when optimizing separately each of the four components of an iterated local search. In particular, when illustrating various important characteristics of one component, we kept the other components fixed. But clearly the optimization of one component depends on the choices made for the others; as an example, we made it clear that a good perturbation must have the property that it cannot be easily undone by the local search. Thus, at least in principle, one should tackle the *global* optimization of an ILS. Since at present there is no theory for analyzing a metaheuristic such as iterated local search, we content ourselves here with just giving a rough idea of how such a global optimization can be approached in practice.

If we reconsider the sub-section on the effect of the initial solution, we see that `GenerateInitialSolution` is to a large extent irrelevant when the ILS performs well and rapidly loses the memory of its starting point. Hereafter we assume that this is the case; then the optimization of `GenerateInitialSolution` can be ignored and we are left with the joint optimization of the three other components. Clearly the best choice of `Perturbation` depends on the choice of `LocalSearch` while the best choice of `AcceptanceCriterion` depends on the

choices of **LocalSearch** and **Perturbation**. In practice, we can approximate this global optimization problem by successively optimizing each component, assuming the others are fixed until no improvements are found for any of the components [26]. Thus the only difference with what has been presented in the previous sub-sections is that the optimization has to be iterative. This does not guarantee global optimization of the ILS, but it should lead to an adequate optimization of the overall algorithm.

Given these approximations, we should make more precise what in fact we are to optimize. For most users, it will be the mean (over starting solutions) of the best cost found during a run of a given length. Then the “best” choice for the different components is a well posed problem, though it is intractable without further restrictions. Furthermore, in general, the detailed instance that will be considered by the user is not known ahead of time, so it is important that the resulting ILS algorithm be robust. Thus it is preferable not to optimize it to the point where it is sensitive to the details of the instance. This robustness seems to be achieved in practice: researchers implement versions of iterated local search with a reasonable level of global optimization, and then test with some degree of success the performance on standard benchmarks.

At the risk of repeating ourselves, let us highlight the main dependencies of the components:

1. the perturbation should not be easily undone by the local search; if the local search has obvious short-comings, a good perturbation should compensate for them.
2. the combination **Perturbation–AcceptanceCriterion** determines the relative balance of intensification and diversification; large perturbations are only useful if they can be accepted, which occurs only if the acceptance criterion is not too biased towards better solutions.

As a general guideline, **LocalSearch** should be as powerful as possible as long as it is not too costly in CPU time. Given such a choice, then find a well adapted perturbation following the discussion in Section 3.2; to the extent possible, take advantage of the structure of the problem. Finally, set the **AcceptanceCriterion** routine so that \mathcal{S}^* is sampled adequately. With this point of view, the overall optimization of the ILS is nearly a bottom-up process, but with iteration. Perhaps the core issue is what to put into **Perturbation**: can one restrict the perturbations to be weak? From a theoretical point of view, the answer to this question depends on whether the best solutions “cluster” in \mathcal{S}^* . In some problems (and the TSP is one of them), there is a strong correlation between the cost of a solution and its “distance” to the optimum: in effect, the best solutions cluster together, i.e., have many similar components. This has been referred to in many different ways: “Massif Central” phenomenon [31], principle of proximate optimality [36], and replica symmetry [64]. If the problem under consideration has this property, it is not unreasonable to hope to find the true optimum using a biased sampling of

\mathcal{S}^* . In particular, it is clear that it is useful to use intensification to improve the probability of hitting the global optimum.

There are, however, other types of problems where the clustering is incomplete, i.e., where very distant solutions can be nearly as good as the optimum. Examples of combinatorial optimization problems in this category are QAP, graph bi-section, and MAX-SAT. When the space of solutions has this property, new strategies have to be used. Clearly, it is still necessary to use intensification to get the best solution in one's current neighborhood, but generally this will not lead to the optimum. After an intensification phase, one must go explore other regions of \mathcal{S}^* . This can be attempted by using "large" perturbations whose strength grows with the instance. Other possibilities are to restart the algorithm from scratch and repeat another intensification phase or by oscillating the acceptance criterion between intensification and diversification phases. Additional ideas on the tradeoffs between intensification and diversification are well discussed in the context of (see, for example, [36]). Clearly, the balance intensification – diversification is very important and is a challenging problem.

4 Selected applications of ILS

ILS algorithms have been applied successfully to a variety of combinatorial optimization problems. In some cases, these algorithms achieve extremely high performance and even constitute the current state-of-the-art metaheuristics, while in other cases the ILS approach is merely competitive with other metaheuristics. In this section we give an overview of interesting ILS applications, presenting the core ideas of these algorithms to illustrate possible uses of ILS. We put a particular emphasis on the traveling salesman problem, given its central role in the development of ILS algorithms.

4.1 ILS for the TSP

The TSP is probably the best-known combinatorial optimization problem. *De facto*, it is a standard test-bed for the development of new algorithmic ideas: a good performance on the TSP is taken as evidence of the value of such ideas. Like for many metaheuristic algorithms, some of the first ILS algorithms were introduced and tested on the TSP, the oldest case of this being due to Baum [8, 7]. He coined his method *iterated descent*; his tests used 2-opt as the embedded heuristic, random 3-changes as the perturbations, and imposed the tour length to decrease (thus the name of the method). His results were not impressive, in part because he considered the non-Euclidean TSP, which is substantially more difficult in practice than the Euclidean TSP.

A major improvement in the performance of ILS algorithms came from the *large-step Markov chain* (LSMC) algorithm proposed by Martin, Otto, and Felten [61]. They used a simulated annealing like acceptance criterion (LSMC) from which the algorithm’s name is derived and considered both the application of **3-opt** local search and the Lin-Kernighan heuristic (LK), which is the best performing local search algorithm for the TSP. But probably the key ingredient of their work is the introduction of the double-bridge move for the perturbation. This choice made the approach very powerful for the Euclidean TSP and encouraged much more work along these lines. In particular, Johnson [45, 46] coined the term “iterated Lin-Kernighan” (ILK) for his implementation of ILS using the Lin-Kernighan as the local search. The main differences with the LSMC implementation are: (i) double-bridge moves are random rather than biased; (ii) the costs are improving (only better tours are accepted, corresponding to the choice **Better** in our notation). Since these initial studies, other ILS variants have been proposed; Johnson and McGeoch [46] give a summary of the situation as of 1997 and several additional ILS variants are covered in the 2002 book chapter [47], which also summarizes results from the 8th DIMACS implementation challenge on the TSP.

A very high performing ILS algorithm is offered as part of the *concorde* software package and it is available for download at <http://www.tsp.gatech.edu/concorde/>. This chained LK code has been developed by Applegate, Bixby, Chvatal, and Cook and a detailed description of the code is given in their recent book on TSP solving [2]; this book also contains details on an extensive computational study of this code. Noteworthy is also the experimental study by Applegate, Cook, and Rohe [1] who performed also tests on very large TSP instances with up to 25 million cities. Recently, a new ILS variant has been proposed that further illustrates the impressive performance of ILS algorithms on very large TSP instances. The iterated Lin-Kernighan variant of Merz and Huhse [63] appears to currently be the best performing algorithms for very large TSP instances with several millions of cities when the computation times are relatively short (in the range of a few hours on a modern PC as of 2008).

A major leap in TSP solving stems from Helsgaun’s LK implementation and its iterated version [40]. The main novelty of Helsgaun’s algorithm lies on the local search side: the LK variant developed is based on more complex basic moves than previous implementations. His iterated version of the LK algorithm is actually not really an ILS algorithm along the lines presented in this chapter since the generation of new starting solutions is through a solution construction method. However, the constructive mechanism is very strongly biased by the incumbent solution, which makes this approach somehow similar to an ILS algorithm. The most recent version of this algorithm, along with an accompanying technical report describing the recent developments, is available for download at <http://www.akira.ruc.dk/~keld/research/LKH/>.

There are a number of other ILS algorithms for the TSP that not necessarily offer the ultimate state-of-the-art performance but that illustrate various ideas that may be useful in ILS algorithms. One algorithm, which has already been mentioned before, is the one by Codenotti et al. [18]. It gives an example of a complex perturbation scheme that is based on the modification of the instance data. Various perturbation sizes as well as population-based extensions of ILS algorithms for the TSP have been studied by Hong et al. [41]. The perturbation mechanism is also the focus of the work by Katayama and Narisha [48]. They introduce a new perturbation mechanism, which they called a *genetic transformation*. The genetic transformation mechanism uses two tours, the best found so far, s_{best}^* , and a second, current local optimum, s' . First a random 4-opt move is performed on s_{best}^* , resulting in s^{*} . Then the subtours that are shared among s^{*} and s' are enumerated and the resulting parts are reconnected with a greedy algorithm. Computational experiments with an iterated LK algorithm using the genetic transformation method instead of the standard double-bridge move have shown that the approach is very effective.

An analysis of the run-time behavior of various ILS algorithms for the TSP is done by Stützle and Hoos in [81, 82]; this analysis clearly shows that ILS algorithms with the **Better** acceptance criterion show a type of stagnation behavior for long run-times. To avoid such stagnation, restarts and a particular acceptance criterion to diversify the search were proposed. The goal of this latter strategy is to force, once search stagnation is detected, the search to continue from a high quality solution that is beyond a certain minimal distance from the current one [81]. As shown in [42], also current state-of-the-art algorithms such as Helsgaun's iterated LK can suffer from stagnation behavior and, hence, their performance can be further improved by similar ideas.

Finally, let us mention that ILS algorithms have been used as components of more complex algorithms. A clear example is the tour merging approach [21, 2]. The central idea is to generate a set G of high quality tours by using ILS and then to post-process these solutions further. In particular, in tour merging the optimal (or, if this is not feasible in reasonable computation time, an as good as possible) tour composed of fragments of tours occurring in G is determined.

4.2 ILS for other problems

ILS algorithms have been applied to a large number of other problems, where often they achieve state-of-the-art performance or are at least very close to it.

Single machine total weighted tardiness problem. Congram, Potts and van de Velde have presented an ILS algorithm for the single machine to-

tal weighted tardiness problem (SMTWTP) [20] based on a dynasearch local search. Their ILS algorithm applies as perturbation a series of random interchange moves and additionally exploits specific properties of the SMTWTP. In the acceptance criterion, Congram et al. introduce a *backtrack step*: after β iterations in which every new local optimum is accepted, the algorithm restarts with the best solution found so far. In our notation, the backtrack step is a particular choice for the history dependence incorporated into the acceptance criterion. The performance of this ILS algorithms was excellent, solving almost all available benchmark instances in few seconds on the then available hardware. A further improvement over this algorithm, mainly based on an enlarged neighborhood being searched in the dynasearch local search was presented by Grosso, Della Croce, and Tadei [37], outperforming the first iterated dynasearch algorithm and, hence, defining the current state of the art for solving the SMTWTP.

Single and parallel machine scheduling. Brucker, Hurink, and Werner [12, 13] apply the principles of ILS to a number of one-machine and parallel-machine scheduling problems. They introduce a local search method which is based on two types of neighborhoods. At each step one goes from one feasible solution to a neighboring one with respect to the secondary neighborhood. The main difference with standard local search methods is that this secondary neighborhood is defined on the set of locally optimal solutions with respect to the first neighborhood. Thus, this is an ILS with two nested neighborhoods; searching in their primary neighborhood corresponds to our local search phase; searching in their secondary neighborhood is like our perturbation phase. The authors also note that the second neighborhood is problem specific; this is what arises in ILS where the perturbation should be adapted to the problem. The search at a higher level reduces the search space and at the same time leads to better results.

Flow shop scheduling. Stützle [79] applied ILS to the flow shop problem (FSP) under the makespan criterion. The algorithm is based on a straightforward first-improvement local search using the insert neighborhood while the perturbation is composed of swap moves, which exchange the positions of two adjacent jobs, and interchange moves, which have no constraint on adjacency. Experimentally, it was found that perturbations with just a few swap and interchange moves were sufficient to obtain very good results. Several acceptance criteria have been compared; the best performing was **ConstTemp**, which corresponds to choosing a constant temperature in the **LSMC** criterion. This ILS algorithm was shown to be among the top performing metaheuristic algorithms for the FSP [74]; an adaptation of this ILS algorithm has also shown very good performance on the flow shop problem with the flowtime objective criterion [27]. The ILS algorithm has also been extended to an iterated greedy (IG) algorithm [75]. The essential idea in IG is to perturb the current solution by a destruction / construction mechanism. In the solution destruction phase, a complete solution is reduced to a partial solution

s_p by removing solution components; in the following construction phase, a complete problem solution is reconstructed starting from s_p by a greedy construction heuristic. Despite the simplicity of the underlying idea, this IG algorithm is a current state-of-the-art algorithm for the FSP [75].

ILS has also been used to solve a flow-shop problem with several stages in series. Yang, Kreipl and Pinedo [88] presented such a method; at each stage, instead of a single machine, there is a group of identical parallel machines. Their metaheuristic has two phases that are repeated iteratively. In the first phase, the operations are assigned to the machines and an initial sequence is constructed. The second phase uses an ILS to find better schedules for each machine at each stage by modifying the sequence of each machine. Yang, Kreipl and Pinedo also proposed a “hybrid” metaheuristic: they first apply a decomposition procedure that solves a series of single stage sub-problems; then they follow this by their ILS. The process is repeated until a satisfactory solution is obtained.

Job shop scheduling. Lourenço [55] and Lourenço and Zwijnenburg [57] used ILS to tackle the job shop scheduling problem (JSP) under the makespan criterion. They performed extensive computational tests, comparing different ways to generate initial solutions, various local search algorithms, different perturbations, and three acceptance criteria. While they found that the initial solution had only a very limited influence, the other components turned out to be very important. Perhaps the heart of their work is the way they perform the perturbations, which has already been described in Section 3.2.

Balas and Vazacopoulos [4] presented a variable depth search heuristic which they called guided local search (GLS). GLS is based on the concept of neighborhood trees, proposed by the authors, where each node corresponds to a solution and the child nodes are obtained by performing an interchange on some critical arc. They developed ILS algorithms by embedding GLS within the shifting bottleneck (SB) procedure and by replacing the reoptimization cycle of SB with a number of cycles of the GLS procedure. They call this procedure SB-GLS1. The later SB-GLS2 variant works as follows. Once all machines have been sequenced, they iteratively remove one machine and apply GLS to a smaller instance defined by the remaining machines. Then again GLS is applied on the initial instance containing *all* machines. Hence, both heuristics are similar in spirit to the one proposed by Lourenço [55] in the sense that they are based on re-optimizing a part of the instance and then reapplying local search to the full one.

Kreipl applied ILS to the total weighted tardiness job shop scheduling problem (TWTJSP) [52]. His ILS algorithm uses a RW acceptance criterion and the local search consists in reversing critical arcs and arcs adjacent to these. One original aspect of this ILS is the perturbation step: Kreipl applies a few steps of a simulated annealing type algorithm with constant temperature and in the perturbation phase a smaller neighborhood than the one used in the local search phase is taken. The number of iterations performed in the perturbation depends how good the incumbent solution is. In promising re-

gions, only a few steps are applied to stay near good solutions, otherwise, a “large” perturbation is applied to escape from a poor region. Computational results with the ILS algorithm on a set of benchmark instances has shown a very promising performance. In fact, the algorithm performs roughly similar to the later proposed, much more complex algorithm by Essafi et al. [29]. Interestingly, this latter approach integrates an ILS algorithm as a local search operator into an evolutionary algorithm, illustrating the fact that ILS can also be used as an improvement method inside other metaheuristics.

Graph bipartitioning. Among the early ILS applications is also the graph bipartitioning problem. Martin and Otto [59, 60] introduced an ILS for this problem following their earlier work on the TSP. For the local search, they used the Kernighan-Lin variable depth local search algorithm (KL) [50] which is the analog for this problem of the LK algorithm. When considering possible perturbations, they noticed a particular weakness of the KL local search: KL frequently generates partitions with many “islands”, i.e., the two sets A and B are typically highly fragmented (disconnected). Thus they introduced perturbations that exchanged vertices between these islands rather than between the whole sets A and B . Finally, for the acceptance criterion, Martin and Otto used the **Better** acceptance criterion. The overall algorithm significantly improved over the embedded local search (random restart of KL); it also improved over simulated annealing if the acceptance criterion was optimized.

MAX-SAT. Battiti and Protasi present an application of *reactive search* to the MAX-SAT problem [5]. Their algorithm consists of two phases: a local search phase and a diversification (perturbation) phase. Because of this, their approach fits perfectly into the ILS framework. Their perturbation is obtained by running a tabu search on the current local minimum so as to guarantee that the modified solution s' is sufficiently different from the current solution s^* . Their measure of difference is just the Hamming distance; the minimum distance is set by the length of a tabu list that is adjusted during the run of the algorithm. For the **LocalSearch**, they use a standard greedy descent local search appropriate for the MAX-SAT problem. Depending on the distance between $s^{*'} and s^* , the tabu list length for the perturbation phase is dynamically adjusted. The next perturbation phase is then started based on solution $s^{*'} — corresponding to the **RW** acceptance criterion. This work illustrates very nicely how one can adjust dynamically the perturbation strength in an ILS run. We conjecture that similar schemes will be useful to adapt the perturbation size while running an ILS algorithm. In later work, Smyth et al. [78] have developed an ILS algorithm that is based on a robust tabu search algorithm that is used in both, the local search phase and the perturbation phase. The main difference in the two phases is that in the perturbation the tabu list length is strongly increased to drive the search away from the current solution. Extensive computational tests showed that this algorithm reaches state-of-the-art performance for a number of MAX-SAT$$

instance classes [78, 42]. Noteworthy is also the ILS algorithm of Yagiura and Ibaraki, which is based on large neighborhoods for MAX-SAT that are searched in the local search phase [87].

Quadratic assignment problem. ILS algorithms have reached also remarkable performance on the quadratic assignment problem (QAP) [80]. Based on the insights gained through an analysis of the run-time behavior of a basic ILS algorithm with the **Better** acceptance criterion, Stützle has proposed a number of different ILS algorithms. Among the highest performing variants have been population-based extensions of ILS that use additional criteria for maintaining diversity of the solutions and restart-type criteria. An extensive experimental campaign has identified this population-based ILS variant as a state-of-the-art algorithm for structured QAP instances.

Other problems. ILS has been applied to a number of other problems and we shortly mention here some further ones without attempting to give an exhaustive overview. A number of ILS approaches for coloring graphs have been proposed [70, 17, 14]; these approaches generally reach very high quality colorings and perform particularly well on some structured graphs. ILS algorithms have also been proposed for various vehicle routing problems (VRPs), including time-dependent routing problems [39], VRPs with time penalty functions [44], the prize-collecting VRP [84], and a multiple depot vehicle scheduling problem [53]. ILS algorithms have also been successfully applied to the car sequencing problem of the 2005 ROADEF challenge, as illustrated by at least two such approaches [23, 71]. ILS is used as a local search procedure inside a GRASP approach by Ribeiro and Urrutia for tackling the mirrored traveling tournament problem [72]. Very high performing ILS algorithms have also been proposed for problems such as maximum clique [49], image registration, a problem arising in in the area of image processing, [24], some loop layout problems [10], linear ordering [19, 76], logistic network design problems [22], learning the structure of Bayesian networks [25] and a capacitated hub location problem [73].

4.3 Summary

The examples we have chosen in this section stress several points that have already been mentioned before. First, the choice of the local search algorithm is usually quite critical if one is to obtain peak performance. In most of the applications, the best performing ILS algorithms apply much more sophisticated local search algorithms than simple best- or first-improvement descent methods. Second, the other components of an ILS also need to be optimized if the state of the art is to be achieved. This optimization should be global, and to succeed should involve the use of problem-specific properties. Examples of this last point were given for instance in the scheduling applications: there

the good perturbations were not simply random moves, rather they involved re-optimizations of significant parts of the instance (c.f. the job shop case).

The final picture we reach is one where (i) ILS is a versatile metaheuristic which can easily be adapted to different combinatorial optimization problems; (ii) sophisticated perturbation schemes and search space diversification are the essential ingredients to achieve the best possible ILS performance.

5 Relation to other metaheuristics

In this section we highlight the similarities and differences between ILS and other well-known metaheuristics. We shall distinguish metaheuristics which are essentially variants of local search and those which generate solutions using a mechanism that is not necessarily based on an explicit neighborhood structure. Among the first class, which we call *neighborhood based metaheuristics*, are methods like simulated annealing (SA) [51, 16], tabu search (TS) [36] or guided local search (GLS) [86]. The second class comprises metaheuristics like GRASP [30], ant colony optimization (ACO) [28], evolutionary and memetic algorithms [3, 65, 67], scatter search [35], variable neighborhood search (VNS) [38, 66] and ILS. Some metaheuristics of this second class, like evolutionary algorithms and ant colony optimization, do not necessarily make use of local search algorithms; however a local search can be embedded in them, in which case the performance is usually enhanced [28, 68, 67]. The other metaheuristics in this class explicitly use embedded local search algorithms as an essential part of their structure. For simplicity, we will assume in what follows that all the metaheuristics of this second class do incorporate local search algorithms. In this case, such metaheuristics generate iteratively input solutions that are passed to a local search; they can thus be interpreted as multi-start algorithms, using the most general meaning of that term. This is why we call them here *multi-start based metaheuristics*.

5.1 Neighborhood based metaheuristics

Neighborhood based metaheuristics are extensions of iterative improvement algorithms and avoid getting stuck in locally optimal solutions by allowing moves to worse solutions in one's neighborhood. Different metaheuristics of this class differ mainly by their move strategies. In the case of simulated annealing, the neighborhood is sampled randomly and worse solutions are accepted with a probability which depends on a temperature parameter and the degree of deterioration incurred; better neighboring solutions are usually accepted while much worse neighboring solutions are accepted with a low probability. In the case of (simple) strategies, the neighborhood is explored

in an aggressive way and cycles are avoided by declaring attributes of visited solutions as tabu. Finally, in the case of guided local search, the evaluation function is dynamically modified by penalizing certain solution components. This allows the search to escape from a solution that is a local optimum of the original objective function.

Obviously, any of these neighborhood based metaheuristics can be used as the `LocalSearch` procedure in ILS. In general, however, those metaheuristics do not halt, so it is necessary to limit their run time if they are to be embedded in ILS. One particular advantage of combining neighborhood based metaheuristics with ILS is that they often obtain much better solutions than iterative descent algorithms. But this advantage usually comes at the cost of larger computation times. Since these metaheuristics allow one to obtain better solutions at the expense of greater computation times, we are confronted with the following optimization problem when using them within an ILS: ⁷ “For how long should one run the embedded search in order to achieve the best tradeoff between computation time and solution quality?” This is very analogous to the question of whether it is best to have a fast but not so effective local search or a slower but more powerful one. The answer depends of course on the total amount of computation time available, and on how the costs improve with time.

A different type of connection between ILS, SA and TS arises from certain similarities in the algorithms. For example, SA can be seen as an ILS without a local search phase (SA samples the original space \mathcal{S} and not the reduced space \mathcal{S}^*) and where the acceptance criteria is $\text{LSMC}(s^*, s^{*'}, \text{history})$. While SA does not employ memory, the use of memory is the main feature of TS which makes a strong use of historical information at multiple levels. Given its effectiveness, we expect this kind of approach for incorporating memory to become widespread in future ILS applications.⁸ Furthermore, TS, as one prototype of a memory intensive search procedure, can be a valuable source of inspiration for deriving ILS variants with a more direct usage of memory; this can lead to a better balance between intensification and diversification in the search.⁹ Similarly, TS strategies may also be improved by features of ILS algorithms and by some insights gained from the research on ILS.

⁷ This question is not specific to ILS; it arises for all multi-start type metaheuristics.

⁸ In early TS publications, proposals similar to the use of perturbations were put forward under the name *random shakeup* [32]. These procedures were characterized as a “randomized series of moves that leads the heuristic (away) from its customary path” [32]. The relationship to perturbations in ILS is obvious.

⁹ Indeed, in [33], Glover uses “strategic oscillation” strategies whereby one cycles over these procedures: the simplest moves are used till there is no more improvement, and then progressively more advanced moves are used.

5.2 *Multi-start based metaheuristics*

Multi-start based metaheuristics can be classified into *constructive* metaheuristics and *perturbation-based* metaheuristics.

Well-known examples of constructive metaheuristics are ant colony optimization and GRASP which both use a probabilistic solution construction phase. An important difference between ACO and GRASP is that ACO has an indirect memory of the search process which is used to bias the construction process, whereas GRASP does not have that kind of memory. An obvious difference between ILS and constructive metaheuristics is that ILS does not construct solutions. However, both generate a sequence of solutions, and if the constructive metaheuristic uses an embedded local search, both go from one local minimum to another. So it might be said that the perturbation phase of an ILS is replaced by a (memory-dependent) construction phase in these constructive metaheuristics. But another connection can be made: ILS can be used instead of the embedded “local search” in an algorithm like ant colony optimization or GRASP. (This is exactly what is also done, for example in [72].) This is one way to generalize ILS, but it is not specific to these kinds of metaheuristics: whenever one has an embedded local search, one can try to replace it by an iterated local search.

Perturbation-based metaheuristics differ in the techniques they use to actually perturb solutions. Before going into details, let us introduce one additional feature for classifying metaheuristics: we will distinguish between population-based algorithms and those that use a single current solution (the population is of size 1). For example, evolutionary algorithms, memetic algorithms, scatter search, and ant colony optimization are population-based, while ILS uses a single solution at each step. Whether or not a metaheuristic is population-based is important for the type of perturbation that can be applied. If no population is used, new solutions are generated by applying perturbations to single solutions; this is what happens for ILS and VNS. If a population is present, one can also use the possibility of recombining several solutions into a new one. Such combinations of solutions are implemented by “crossover” operators in evolutionary algorithms or in the recombination of multiple solutions in scatter search.

In general, population-based metaheuristics are more complex to use than those following a single solution: they require mechanisms to manage a population of solutions and more importantly it is necessary to find effective operators for the combination of solutions. Most often, this last task is a real challenge. The complexity of these population-based local search hybrid methods can be justified if they lead to better performance than non-population based methods. Therefore, one question of interest is whether using a population of solutions is really useful. Clearly for some problems such as the TSP with high cost-distance correlations, the use of a single element in the population leads to good results, so the advantage of population-based methods is small or may become only noticeable if very high computation times are invested.

However, for other problems (with less cost-distance correlations), the use of a population can be an appealing way to achieve search space diversification. Thus, population based methods may be desirable if their complexity is not overwhelming. Because of this, population-based extensions of ILS are promising approaches.

To date, several population-based extensions of ILS *have* been proposed [41, 82, 80, 85]. The approaches proposed in [41, 82] keep the simplicity of ILS algorithms by maintaining unchanged the perturbations: one parent is perturbed to give one child. More complex population-based ILS extensions with mechanisms for maintaining diversity in the population are considered in [80]. A population of solutions is used in [85] to restrict the perturbation to explore only parts of solutions where pairs of solutions differ (similar in spirit to the genetic transformations [48]) and to reduce the size of the neighborhood searched in the local search.

Finally, let us discuss VNS, which is the metaheuristic closest to ILS. VNS begins by observing that the concept of local optimality is conditional on the neighborhood structure used in a local search. Then VNS systemizes the idea of changing the neighborhood during the search to avoid getting stuck in poor quality solutions. Several VNS variants have been proposed. The most widely used one, *basic VNS*, can, in fact, be seen as an ILS algorithm which uses the **Better** acceptance criterion and a systematic way of varying the perturbation strength. To do so, basic VNS orders neighborhoods as $\mathcal{N}_1, \dots, \mathcal{N}_m$ where the order is chosen according to the neighborhood size. Let k be a counter variable, $k = 1, 2, \dots, m$, and initially set $k = 1$. If the perturbation and the subsequent local search lead to a new best solution, then k is reset to 1, otherwise k is increased by one. We refer to [38] for a description of other VNS variants.

A major difference between ILS and VNS is the philosophy underlying the two metaheuristics: ILS explicitly has the goal of building a walk in the set of locally optimal solutions, while VNS algorithms are derived from the idea of systematically changing neighborhoods during the search.

Clearly, there are major points in common between most of today's high performance metaheuristics. How can one summarize how iterated local search differs from the others? We shall proceed by enumeration as the diversity of today's metaheuristics seems to forbid any simpler approach. When comparing to ACO and GRASP, we see that ILS uses perturbations to create new solutions; this is quite different in principle and in practice from using construction. When comparing to evolutionary algorithms, memetic algorithms, and scatter search, we see that ILS, as we defined it, has a population size of 1; therefore no recombination operators need be defined. We could continue like this, but we cannot expect the boundaries between all metaheuristics to be so clear-cut. Not only are hybrid methods very often the way to go, but most often one can smoothly go from one metaheuristic to another. In addition, as mentioned at the beginning of this chapter, the distinction between heuristic and metaheuristic is rarely unambiguous. So our

point of view is not that iterated local search has essential features that are absent in other metaheuristics; rather, when considering the basic structure of iterated local search, some simple yet powerful ideas transpire, and these can be of use in most metaheuristics, being close or not in spirit to iterated local search.

6 Conclusions

ILS has many of the desirable features of a metaheuristic: it is simple, easy to implement, robust, and highly effective. The essential idea of ILS lies in focusing the search not on the full space of solutions but on a smaller subspace defined by the solutions that are locally optimal for a given optimization engine. The success of ILS lies in the *biased* sampling of this set of local optima. How effective this approach turns out to be depends mainly on the choice of the local search, the perturbations, and the acceptance criterion. Interestingly, even when using the most naïve implementations of these parts, ILS can do much better than random restart. But with further work so that the different modules are well adapted to the problem at hand, ILS can often become a competitive or even state-of-the-art algorithm. This dichotomy is important because the optimization of the algorithm can be done progressively, and so ILS can be kept at any desired level of simplicity. This, plus the modular nature of iterated local search, leads to short development times and gives ILS an edge over more complex metaheuristics in the world of industrial applications. As an example of this, recall that ILS essentially treats the embedded heuristic as a black box; then upgrading an ILS to take advantage of a new and better local search algorithm is nearly immediate. Because of all these features, we believe that ILS is a promising and powerful algorithm to solve real complex problems in industry and services, in areas ranging from finance to production management and logistics. Finally, let us note that although all of the present review was given in the context of tackling combinatorial optimization problems, in reality much of what we covered can be extended in a straight-forward manner to continuous optimization problems.

Looking ahead towards future research directions, we expect ILS to be applied to new kinds of problems. Some challenging examples are: (i) problems where the constraints are very severe and so most metaheuristics fail; (ii) multi-objective problems, bringing one closer to real problems; (iii) dynamic or real-time problems where the problem data vary during the solution process.

The ideas and results presented in this chapter leave many questions unanswered. Clearly, more work needs to be done to better understand the interplay between the ILS modules `GenerateInitialSolution`, `Perturbation`, `LocalSearch`, and `AcceptanceCriterion`. Other directions for improving ILS performance are to consider the intelligent use of memory, explicit intensification

and diversification strategies, and greater problem-specific tuning. The exploration of these issues will certainly lead to higher performance iterated local search algorithms.
